
7 Voronoi Diagrams

The Post Office Problem

Suppose you are on the advisory board for the planning of a supermarket chain, and there are plans to open a new branch at a certain location. To predict whether the new branch will be profitable, you must estimate the number of customers it will attract. For this you have to model the behavior of your potential customers: how do people decide where to do their shopping? A similar question arises in social geography, when studying the economic activities in a country: what is the trading area of certain cities? In a more abstract set-

Figure 7.1
The trading areas of the capitals of the twelve provinces in the Netherlands, as predicted by the Voronoi assignment model

ting we have a set of central places—called *sites*—that provide certain goods or services, and we want to know for each site where the people live who obtain their goods or services from that site. (In computational geometry the sites are traditionally viewed as post offices where customers want to post their letters—hence the subtitle of this chapter.) To study this question we make the following simplifying assumptions:

- the price of a particular good or service is the same at every site;

- the cost of acquiring the good or service is equal to the price plus the cost of transportation to the site;
- the cost of transportation to a site equals the Euclidean distance to the site times a fixed price per unit distance;
- consumers try to minimize the cost of acquiring the good or service.

Usually these assumptions are not completely satisfied: goods may be cheaper at some sites than at others, and inside a city the transportation cost from one point to another is probably not linear in the Euclidean distance between the points. But the model above can give a rough approximation of the trading areas of the sites. Areas where the behavior of the people differs from that predicted by the model can be subjected to further research, to see what caused the different behavior.

Our interest lies in the geometric interpretation of the model above. The assumptions in the model induce a subdivision of the total area under consideration into regions—the trading areas of the sites—such that the people who live in the same region all go to the same site. Our assumptions imply that people simply get their goods at the nearest site—a fairly realistic situation. This means that the trading area for a given site consists of all those points for which that site is closer than any other site. Figure 7.1 gives an example. The sites in this figure are the capitals of the twelve provinces in the Netherlands.

The model where every point is assigned to the nearest site is called the *Voronoi assignment model*. The subdivision induced by this model is called the *Voronoi diagram* of the set of sites. From the Voronoi diagram we can derive all kinds of information about the trading areas of the sites and their relations. For example, if the regions of two sites have a common boundary then these two sites are likely to be in direct competition for customers that live in the boundary region.

The Voronoi diagram is a versatile geometric structure. We have described an application to social geography, but the Voronoi diagram has applications in physics, astronomy, robotics, and many more fields. It is also closely linked to another important geometric structure, the so-called Delaunay triangulation, which we shall encounter in Chapter 9. In the current chapter we shall confine ourselves to the basic properties and the construction of the Voronoi diagram of a set of point sites in the plane.

7.1 Definition and Basic Properties

Denote the Euclidean distance between two points p and q by $\text{dist}(p, q)$. In the plane we have

$$\text{dist}(p, q) := \sqrt{(p_x - q_x)^2 + (p_y - q_y)^2}.$$

Let $P := \{p_1, p_2, \dots, p_n\}$ be a set of n distinct points in the plane; these points are the sites. We define the Voronoi diagram of P as the subdivision of the plane into n cells, one for each site in P , with the property that a point q lies in the cell corresponding to a site p_i if and only if $\text{dist}(q, p_i) < \text{dist}(q, p_j)$ for each $p_j \in P$ with $j \neq i$. We denote the Voronoi diagram of P by $\text{Vor}(P)$. The cell that corresponds to a site p_i is denoted $V(p_i)$; we call it the Voronoi cell of p_i . (In the terminology of the introduction to this chapter: $V(p_i)$ is the trading area of site p_i .)

We now take a closer look at the Voronoi diagram. First we study the structure of a single Voronoi cell. For two points p and q in the plane we define the *bisector of p and q* as the perpendicular bisector of the line segment \overline{pq} . This bisector splits the plane into two half-planes. We denote the open half-plane that contains p by $h(p, q)$ and the open half-plane that contains q by $h(q, p)$. Notice that $r \in h(p, q)$ if and only if $\text{dist}(r, p) < \text{dist}(r, q)$. From this we obtain the following observation.

Observation 7.1 $V(p_i) = \bigcap_{1 \leq j \leq n, j \neq i} h(p_i, p_j)$.

Thus $V(p_i)$ is the intersection of $n - 1$ half-planes and, hence, a (possibly unbounded) open convex polygonal region bounded by at most $n - 1$ vertices and at most $n - 1$ edges.

What does the complete Voronoi diagram look like? We just saw that each cell of the diagram is the intersection of a number of half-planes, so the Voronoi diagram is a planar subdivision whose edges are straight line segments. Some edges are line segments and others are half-lines. Unless all sites are collinear there will be no edges that are full lines:

Theorem 7.2 *Let P be a set of n point sites in the plane. If all the sites are collinear then $\text{Vor}(P)$ consists of $n - 1$ parallel lines and n cells. Otherwise, $\text{Vor}(P)$ is connected and its edges are either segments or half-lines.*

Proof. The first part of the theorem is easy to prove, so assume that not all sites in P are collinear.

We first show that the edges of $\text{Vor}(P)$ are either segments or half-lines. We already know that the edges of $\text{Vor}(P)$ are parts of straight lines, namely parts of the bisectors between pairs of sites. Now suppose for a contradiction that there is an edge e of $\text{Vor}(P)$ that is a full line. Let e be on the boundary of the Voronoi cells $V(p_i)$ and $V(p_j)$. Let $p_k \in P$ be a point that is not collinear with p_i and p_j . The bisector of p_j and p_k is not parallel to e and, hence, it intersects e . But then the part of e that lies in the interior of $h(p_k, p_j)$ cannot be on the boundary of $V(p_j)$, because it is closer to p_k than to p_j , a contradiction.

It remains to prove that $\text{Vor}(P)$ is connected. If this were not the case then there would be a Voronoi cell $V(p_i)$ splitting the plane into two. Because Voronoi cells are convex, $V(p_i)$ would consist of a strip bounded by two parallel full lines. But we just proved that the edges of the Voronoi diagram cannot be full lines, a contradiction. \square

Now that we understand the structure of the Voronoi diagram we investigate its complexity, that is, the total number of its vertices and edges. Since there are n sites and each Voronoi cell has at most $n - 1$ vertices and edges, the complexity of $\text{Vor}(P)$ is at most quadratic. It is not clear, however, whether $\text{Vor}(P)$ can actually have quadratic complexity: it is easy to construct an example where a single Voronoi cell has linear complexity, but can it happen that many cells have linear complexity? The following theorem shows that this is not the case and that the average number of vertices of the Voronoi cells is less than six.

Theorem 7.3 *The number of vertices in the Voronoi diagram of a set of n point sites in the plane is at most $2n - 5$ and the number of edges is at most $3n - 6$.*

Proof. If the sites are all collinear then the theorem immediately follows from Theorem 7.2, so assume this is not the case. We prove the theorem using *Euler's formula*, which states that for any connected planar embedded graph with m_v nodes, m_e arcs, and m_f faces the following relation holds:

$$m_v - m_e + m_f = 2.$$

We cannot apply Euler's formula directly to $\text{Vor}(P)$, because $\text{Vor}(P)$ has half-infinite edges and is therefore not a proper graph. To remedy the situation we add one extra vertex v_∞ "at infinity" to the set of vertices and we consider all half-infinite edges of $\text{Vor}(P)$ to be connected to this vertex. We now have a connected planar graph to which we can apply Euler's formula. We obtain the following relation between n_v , the number of vertices of $\text{Vor}(P)$, n_e , the number of edges of $\text{Vor}(P)$, and n , the number of sites:

$$(n_v + 1) - n_e + n = 2. \tag{7.1}$$

Moreover, every edge in the augmented graph has exactly two vertices, so if we sum the degrees of all vertices we get twice the number of edges. Because every vertex, including v_∞ , has degree at least three we get

$$2n_e \geq 3(n_v + 1). \tag{7.2}$$

Together with equation (7.1) this implies the theorem. \square

We close this section with a characterization of the edges and vertices of the Voronoi diagram. We know that the edges are parts of bisectors of pairs of sites and that the vertices are intersection points between these bisectors. There is a quadratic number of bisectors, whereas the complexity of the $\text{Vor}(P)$ is only linear. Hence, not all bisectors define edges of $\text{Vor}(P)$ and not all intersections are vertices of $\text{Vor}(P)$. To characterize which bisectors and intersections define features of the Voronoi diagram we make the following definition. For a point q we define the *largest empty circle of q with respect to P* , denoted by $C_P(q)$, as the largest circle with q as its center that does not contain any site of P in its interior. The following theorem characterizes the vertices and edges of the Voronoi diagram.

Theorem 7.4 For the Voronoi diagram $\text{Vor}(P)$ of a set of points P the following holds:

- (i) A point q is a vertex of $\text{Vor}(P)$ if and only if its largest empty circle $C_P(q)$ contains three or more sites on its boundary.
- (ii) The bisector between sites p_i and p_j defines an edge of $\text{Vor}(P)$ if and only if there is a point $q \in \mathbb{E}^2$ such that $C_P(q)$ contains both p_i and p_j on its boundary but no other site.

Proof. (i) Suppose there is a point q such that $C_P(q)$ contains three or more sites on its boundary. Let $p_i, p_j,$ and p_k be three of those sites. Since the interior of $C_P(q)$ is empty q must be on the boundary of each of $V(p_i), V(p_j),$ and $V(p_k),$ and q must be a vertex of $\text{Vor}(P)$.

On the other hand, every vertex q of $\text{Vor}(P)$ is incident to at least three edges and, hence, to at least three Voronoi cells $V(p_i), V(p_j),$ and $V(p_k)$. Vertex q must be equidistant to $p_i, p_j,$ and p_k and there cannot be another site closer to $q,$ since otherwise $V(p_i), V(p_j),$ and $V(p_k)$ would not meet at $q.$ Hence, the interior of the circle with $p_i, p_j,$ and p_k on its boundary does not contain any site.

- (ii) Suppose there is a point q with the property stated in the theorem. Since $C_P(q)$ does not contain any sites in its interior and p_i and p_j are on its boundary, we have $\text{dist}(q, p_i) = \text{dist}(q, p_j) \leq \text{dist}(q, p_k)$ for all $1 \leq k \leq n.$ It follows that q lies on an edge or vertex of $\text{Vor}(P).$ The first part of the theorem implies that q cannot be a vertex of $\text{Vor}(P).$ Hence, q lies on an edge of $\text{Vor}(P),$ which is defined by the bisector of p_i and $p_j.$

Conversely, let the bisector of p_i and p_j define a Voronoi edge. The largest empty circle of any point q in the interior of this edge must contain p_i and p_j on its boundary and no other sites.

□

7.2 Computing the Voronoi Diagram

In the previous section we studied the structure of the Voronoi diagram. We now set out to compute it. Observation 7.1 suggests a simple way to do this: for each site $p_i,$ compute the common intersection of the half-planes $h(p_i, p_j),$ with $j \neq i,$ using the algorithm presented in Chapter 4. This way we spend $O(n \log n)$ time per Voronoi cell, leading to an $O(n^2 \log n)$ algorithm to compute the whole Voronoi diagram, assuming we can assemble the cells to get the diagram. Can't we do better? After all, the total complexity of the Voronoi diagram is only linear. The answer is yes: the plane sweep algorithm described below—commonly known as *Fortune's algorithm* after its inventor—computes the Voronoi diagram in $O(n \log n)$ time. You may be tempted to look for an even faster algorithm, for example one that runs in linear time. This turns out to be too much to ask: the problem of sorting n real numbers is reducible to the problem of computing Voronoi diagrams, so any algorithm for computing

Voronoi diagrams must take $\Omega(n \log n)$ time in the worst case. Hence, Fortune's algorithm is optimal.

The strategy in a plane sweep algorithm is to sweep a horizontal line—the *sweep line*—from top to bottom over the plane. While the sweep is performed information is maintained regarding the structure that one wants to compute. More precisely, information is maintained about the intersection of the structure with the sweep line. While the sweep line moves downwards the information does not change, except at certain special points—the *event points*.

Let's try to apply this general strategy to the computation of the Voronoi diagram of a set $P = \{p_1, p_2, \dots, p_n\}$ of point sites in the plane. According to the plane sweep paradigm we move a horizontal sweep line ℓ from top to bottom over the plane. The paradigm involves maintaining the intersection of the Voronoi diagram with the sweep line. Unfortunately this is not so easy, because the part of $\text{Vor}(P)$ above ℓ depends not only on the sites that lie above ℓ but also on sites below ℓ . Stated differently, when the sweep line reaches the topmost vertex of the Voronoi cell $V(p_i)$ it has not yet encountered the corresponding site p_i . Hence, we do not have all the information needed to compute the vertex. We are forced to apply the plane sweep paradigm in a slightly different fashion: instead of maintaining the intersection of the Voronoi diagram with the sweep line, we maintain information about the part of the Voronoi diagram of the sites above ℓ that cannot be changed by sites below ℓ .

Denote the closed half-plane above ℓ by ℓ^+ . What is the part of the Voronoi diagram above ℓ that cannot be changed anymore? In other words, for which points $q \in \ell^+$ do we know for sure what their nearest site is? The distance of a point $q \in \ell^+$ to any site below ℓ is greater than the distance of q to ℓ itself. Hence, the nearest site of q cannot lie below ℓ if q is at least as near to some site $p_i \in \ell^+$ as q is to ℓ . The locus of points that are closer to some site $p_i \in \ell^+$ than to ℓ is bounded by a parabola. Hence, the locus of points that are closer to any site above ℓ than to ℓ itself is bounded by parabolic arcs. We call this sequence of parabolic arcs the *beach line*. Another way to visualize the beach line is the following. Every site p_i above the sweep line defines a complete parabola β_i . The beach line is the function that—for each x -coordinate—passes through the lowest point of all parabolas.

Observation 7.5 *The beach line is x -monotone, that is, every vertical line intersects it in exactly one point.*

It is easy to see that one parabola can contribute more than once to the beach line. We'll worry later about how many pieces there can be. Notice that the *breakpoints* between the different parabolic arcs forming the beach line lie on edges of the Voronoi diagram. This is not a coincidence: the breakpoints exactly trace out the Voronoi diagram while the sweep line moves from top to bottom. These properties of the beach line can be proved using elementary geometric arguments.

So, instead of maintaining the intersection of $\text{Vor}(P)$ with ℓ we maintain the beach line as we move our sweep line ℓ . We do not maintain the beach line

explicitly, since it changes continuously as ℓ moves. For the moment let's ignore the issue of how to represent the beach line until we understand where and how its combinatorial structure changes. This happens when a new parabolic arc appears on it, and when a parabolic arc shrinks to a point and disappears.

First we consider the events where a new arc appears on the beach line. One occasion where this happens is when the sweep line ℓ reaches a new site. The parabola defined by this site is at first a degenerate parabola with zero width: a vertical line segment connecting the new site to the beach line. As the sweep line continues to move downward the new parabola gets wider and wider. The part of the new parabola below the old beach line is now a part of the new beach line. Figure 7.2 illustrates this process. We call the event where a new site is encountered a *site event*.

Section 7.2
COMPUTING THE VORONOI
DIAGRAM

Figure 7.2
A new arc appears on the beach line because a site is encountered

What happens to the Voronoi diagram at a site event? Recall that the break-points on the beach line trace out the edges of the Voronoi diagram. At a site event two new breakpoints appear, which start tracing out edges. In fact, the new breakpoints coincide at first, and then move in opposite directions to trace out the same edge. Initially, this edge is not connected to the rest of the Voronoi diagram above the sweep line. Later on—we will see shortly exactly when this will happen—the growing edge will run into another edge, and it becomes connected to the rest of the diagram.

So now we understand what happens at a site event: a new arc appears on the beach line, and a new edge of the Voronoi diagram starts to be traced out. Is it possible that a new arc appears on the beach line in any other way? The answer is no:

Lemma 7.6 *The only way in which a new arc can appear on the beach line is through a site event.*

Proof. Suppose for a contradiction that an already existing parabola β_j defined by a site p_j breaks through the beach line. There are two ways in which this could happen.

The first possibility is that β_j breaks through in the middle of an arc of a parabola β_i . The moment this is about to happen, β_i and β_j are tangent, that is, they have exactly one point of intersection. Let ℓ_y denote the y -coordinate of the sweep line at the moment of tangency. If $p_j := (p_{j,x}, p_{j,y})$, then the parabola β_j is given by

$$\beta_j := y = \frac{1}{2(p_{j,y} - \ell_y)}(x^2 - 2p_{j,x}x + p_{j,x}^2 + p_{j,y}^2 - \ell_y^2).$$

The formula for β_j is similar, of course. Using that both $p_{j,y}$ and $p_{i,y}$ are larger than ℓ_y , it is easy to show that it is impossible that β_i and β_j have only one point of intersection. Hence, a parabola β_j never breaks through in the middle of an arc of another parabola β_i .

The second possibility is that β_j appears in between two arcs. Let these arcs be part of parabolas β_i and β_k . Let q be the intersection point of β_i and β_k at which β_j is about to appear on the beach line, and assume that β_i is on the beach line left of q and β_k is on the beach line right of q , as in Figure 7.3. Then there is a circle C that passes through p_i , p_j , and p_k , the sites defining the parabolas. This circle is also tangent to the sweep line ℓ at some point p_ℓ . The cyclic clockwise order on C is p_ℓ, p_i, p_j, p_k , because β_j is assumed to appear in between the arcs of β_i and β_k . Consider an infinitesimal motion of the sweep line downward while keeping the circle C tangent to ℓ ; see Figure 7.3. Then C cannot have empty interior and still pass through p_j : either p_i or p_k

Figure 7.3
The situation when β_j would appear on the beach line, and the circle when the sweep line has proceeded

will penetrate the interior. Therefore, in a sufficiently small neighborhood of q the parabola β_j cannot appear on the beach line when the sweep line moves downward, because either p_i or p_k will be closer to ℓ than p_j . \square

An immediate consequence of the lemma is that the beach line consists of at most $2n - 1$ parabolic arcs: each site encountered gives rise to one new arc and the splitting of at most one existing arc into two, and there is no other way an arc can appear on the beach line.

Figure 7.4
An arc disappears from the beach line

The second type of event in the plane sweep algorithm is where an existing arc of the beach line shrinks to a point and disappears, as in Figure 7.4. Let

α' be the disappearing arc, and let α and α'' be the two neighboring arcs of α' before it disappears. The arcs α and α'' cannot be part of the same parabola; this possibility can be excluded in the same way as the first possibility in the proof of Lemma 7.6 was excluded. Hence, the three arcs α , α' , and α'' are defined by three distinct sites p_i , p_j , and p_k . At the moment α' disappears, the parabolas defined by these three sites pass through a common point q . Point q is equidistant from ℓ and each of the three sites, and there is a circle passing through p_i , p_j , and p_k with q as its center whose lowest point lies on ℓ . There cannot be a site in the interior of this circle: such a site would be closer to q than q is to ℓ , contradicting the fact that q is on the beach line. It follows that the point q is a vertex of the Voronoi diagram. This is not very surprising, since we observed earlier that the breakpoints on the beach line trace out the Voronoi diagram. So when an arc disappears from the beach line and two breakpoints meet, two edges of the Voronoi diagram meet as well. We call the event where the sweep line reaches the lowest point of a circle through three sites defining consecutive arcs on the beach line a *circle event*. From the above we can conclude the following lemma.

Lemma 7.7 *The only way in which an existing arc can disappear from the beach line is through a circle event.*

Now we know where and how the combinatorial structure of the beach line changes: at a site event a new arc appears, and at a circle event an existing arc drops out. We also know how this relates to the Voronoi diagram under construction: at a site event a new edge starts to grow, and at a circle event two growing edges meet to form a vertex. It remains to find the right data structures to maintain the necessary information during the sweep. Our goal is to compute the Voronoi diagram, so we need a data structure that stores the part of the Voronoi diagram computed thus far. We also need the two ‘standard’ data structures for any sweep line algorithm: an event queue and a structure that represents the status of the sweep line. Here the latter structure is a representation of the beach line. These data structures are implemented in the following way.

- We store the Voronoi diagram under construction in our usual data structure for subdivisions, the doubly-connected edge list. A Voronoi diagram, however, is not a true subdivision as defined in Chapter 2: it has edges that are half-lines or full lines, and these cannot be represented in a doubly-connected edge list. During the construction this is not a problem, because the representation of the beach line—described next—will make it possible to access the relevant parts of the doubly-connected edge list efficiently during its construction. But after the computation is finished we want to have a valid doubly-connected edge list. To this end we add a big bounding box to our scene, which is large enough so that it contains all vertices of the Voronoi diagram. The final subdivision we compute will then be the bounding box plus the part of the Voronoi diagram inside it.
- The beach line is represented by a balanced binary search tree T ; it is

the status structure. Its leaves correspond to the arcs of the beach line—which is x -monotone—in an ordered manner: the leftmost leaf represents the leftmost arc, the next leaf represents the second leftmost arc, and so on. Each leaf μ stores the site that defines the arc it represents. The internal nodes of T represent the breakpoints on the beach line. A breakpoint is stored at an internal node by an ordered tuple of sites $\langle p_i, p_j \rangle$, where p_i defines the parabola left of the breakpoint and p_j defines the parabola to the right. Using this representation of the beach line, we can find in $O(\log n)$ time the arc of the beach line lying above a new site. At an internal node, we simply compare the x -coordinate of the new site with the x -coordinate of the breakpoint, which can be computed from the tuple of sites and the position of the sweep line in constant time. (Note that we do not explicitly store the parabolas.)

In T we also store pointers to the other two data structures used during the sweep. Each leaf of T , representing an arc α , stores one pointer to a node in the event queue, namely, the node that represents the circle event in which α will disappear. Finally, every internal node has a pointer to a half-edge in the Voronoi diagram that is being traced out by the breakpoint it represents.

- The event queue Q is implemented as a priority queue, where the priority of an event is its y -coordinate. It stores the upcoming events that are already known. For a site event we simply store the site itself. For a circle event the event point that we store is the lowest point of the circle. For a circle event we also store a pointer to the leaf in T that represents the arc that will disappear in the event.

All the site events are known in advance, unlike the circle events. This brings us to one final issue that we must discuss, namely the detection of the circle events. Recall that a circle event is caused by the disappearance of an arc from the beach line. Let α, α' and α'' be three consecutive arcs on the beach line, and assume that the circle event causes α' to disappear. This happens exactly when the three sites p_i, p_j , and p_k defining these arcs, define a circle $C(p_i, p_j, p_k)$ whose lowest point lies on the sweep line.

Our algorithm will make sure that for every three consecutive arcs on the beach line, the corresponding circle event is in the event queue Q if the circle intersects the sweep line. If the circle lies completely above the sweep line, then the event has already been dealt with. Also if the circle contains some other site in its interior the event should not be handled. In both cases the circle event isn't and shouldn't be in the event queue.

Lemma 7.8 *Every Voronoi vertex is detected by means of a circle event.*

Proof. For a Voronoi vertex q , let p_i, p_j , and p_k be the three sites through which a circle $C(p_i, p_j, p_k)$ passes with no sites in the interior. By Theorem 7.4, such a circle and three sites indeed exist. For simplicity we only prove the case where no other sites lie on $C(p_i, p_j, p_k)$, and the lowest point of $C(p_i, p_j, p_k)$ is not one of the defining sites. Assume without loss of generality that from the

lowest point of $C(p_i, p_j, p_k)$, the clockwise traversal of $C(p_i, p_j, p_k)$ encounters the sites p_i, p_j, p_k in this order.

We must show that just before the sweep line reaches the lowest point of $C(p_i, p_j, p_k)$, there are three consecutive arcs α, α' and α'' on the beach line defined by the sites p_i, p_j , and p_k . Only then will the circle event take place. Consider the sweep line an infinitesimal amount before it reaches the lowest point of $C(p_i, p_j, p_k)$. Since $C(p_i, p_j, p_k)$ doesn't contain any other sites inside or on it, there exists a circle through p_i and p_j that is tangent to the sweep line, and doesn't contain sites in the interior. So there are adjacent arcs on the beach line defined by p_i and p_j . Similarly, there are adjacent arcs on the beach line defined by p_j and p_k . It is easy to see that the two arcs defined by p_j are actually the same arc, and it follows that there are three consecutive arcs on the beach line defined by p_i, p_j , and p_k . Therefore, the corresponding circle event is in Q just before the event takes place, and the Voronoi vertex is detected. \square

During the sweep the beach line changes its topological structure at every event. This means that new triples of consecutive arcs can show up at all events. At a site event, a new arc appears on the beach line and there will be new consecutive triples including that arc. At a circle event, an arc disappears from the beach line, and the neighboring arcs define new triples. Furthermore, the events can destroy triples of consecutive arcs. When an arc disappears at a circle event, all other triples involving that arc don't correspond to consecutive triples on the beach line anymore. When a new arc appears at a site event, another arc is split and triples involving the split arc may be destroyed.

Note that it is not true that circle events in Q will actually take place later on. A circle event will only take place if the triple of consecutive arcs lives on until the sweep line reaches the lowest point of the circle. Circle events that are deleted before they take place are also called false alarms.

Let's summarize. The event queue Q contains a circle event if and only if there are three consecutive arcs on the beach line such that the circle through the sites defining the three arcs intersects the sweep line, and hasn't been deleted yet. Maintaining this invariant involves both insertions and deletions of circle events when the beach line changes its structure, that is, when other events are handled.

When there is a new triple of consecutive arcs, we first test whether these arcs are defined by three different sites. If only two sites are involved, we ignore the new triple: it cannot define a circle event. If three sites are involved, we test whether the circle event isn't in Q yet and the circle intersects the sweep line. If so, we insert the circle event; otherwise, we ignore it.

When a triple of consecutive arcs is destroyed, we delete the corresponding circle event from Q , if it occurs in Q . Suppose that an arc α disappears from the beach line, or it is split, and we wish to delete all circle events α participates in—see Figure 7.5. We first search in T for the leaf μ storing the site defining α . At that leaf there is a pointer to a circle event in Q , which is removed from Q . The other two circle events α may participate in can be found through the

Section 7.2
COMPUTING THE VORONOI
DIAGRAM

Figure 7.5
When an arc α defined by p_j disappears, three circle events in Q may be destroyed.

previous leaf and the next leaf in T . These leaves also have a pointer to a node in Q , which must be deleted. Finally, the leaf μ is deleted from T .

We can now describe the plane sweep algorithm in detail. Notice that after all events have been handled and the event queue Q is empty, the beach line hasn't disappeared yet. The breakpoints that are still present correspond to the half-infinite edges of the Voronoi diagram. As stated earlier, a doubly connected edge list cannot represent half-infinite edges, so we must add a bounding box to the scene to which these edges can be attached. The overall structure of the algorithm is as follows.

Algorithm VORONOIDIAGRAM(P)

Input. A set $P := \{p_1, \dots, p_n\}$ of point sites in the plane.

Output. The Voronoi diagram $\text{Vor}(P)$ given inside a bounding box in a doubly-connected edge list structure.

1. Initialize the event queue Q with all site events.
2. **while** Q is not empty
3. **do** Consider the event with largest y-coordinate in Q .
4. **if** the event is a site event, occurring at site p_i
5. **then** HANDLESITEEVENT(p_i)
6. **else** HANDLECIRCLEEVENT(p_ℓ), where p_ℓ is the lowest point of the circle causing the event
7. Remove the event from Q .
8. The internal nodes still present in T correspond to the half-infinite edges of the Voronoi diagram. Compute a bounding box that contains all vertices of the Voronoi diagram in its interior, and attach the half-infinite edges to the bounding box by updating the doubly-connected edge list appropriately.
9. Traverse the half-edges of the doubly-connected edge list to add the cell records and the pointers to and from them.

The procedures to handle the events are defined as follows.

HANDLESITEEVENT(p_i)

1. Search in T for the arc α vertically above p_i , and delete all circle events involving α from Q .
2. Replace the leaf of T that represents α with a subtree having three leaves. The middle leaf stores the new site p_i and the other two leaves store the site p_j that was originally stored with α . Store the tuples $\langle p_j, p_i \rangle$ and $\langle p_i, p_j \rangle$ representing the new breakpoints at the two new internal nodes. Perform rebalancing operations on T if necessary.
3. Create new records in the Voronoi diagram structure for the two half-edges separating $V(p_i)$ and $V(p_j)$, which will be traced out by the two new breakpoints.
4. Check the triples of consecutive arcs involving one of the three new arcs. Insert the corresponding circle event only if the circle intersects the sweep line and the circle event isn't present yet in Q .

HANDLECIRCLEEVENT(p_ℓ)

1. Search in T for the arc α vertically above p_ℓ that is about to disappear, and delete all circle events that involve α from Q .
2. Delete the leaf that represents α from T . Update the tuples representing the breakpoints at the internal nodes. Perform rebalancing operations on T if necessary.
3. Add the center of the circle causing the event as a vertex record in the Voronoi diagram structure and create two half-edge records corresponding to the new breakpoint of the Voronoi diagram. Set the pointers between them appropriately.
4. Check the new triples of consecutive arcs that arise because of the disappearance of α . Insert the corresponding circle event into Q only if the circle intersects the sweep line and the circle event isn't present yet in Q .

Lemma 7.9 *The algorithm runs in $O(n \log n)$ time and it uses $O(n)$ storage.*

Proof. The primitive operations on the tree T and the event queue Q , such as inserting or deleting an element, take $O(\log n)$ time each. The primitive operations on the doubly-connected edge list take constant time. To handle an event we do a constant number of such primitive operations, so we spend $O(\log n)$ time to process an event. Obviously, there are n site events. As for the number of circle events, we observe that every such event that is processed defines a vertex of $\text{Vor}(P)$. Note that false alarms are deleted from Q before they are processed. They are created and deleted while processing another, real event, and the time we spend on them is subsumed under the time we spend to process this event. Hence, the number of circle events that we process is at most $2n - 5$. The time and storage bounds follow. \square

Before we state the final result of this section we should say a few words about degenerate cases.

The algorithm handles the events from top to bottom, so there is a degeneracy when two or more events lie on a common horizontal line. This happens,

for example, when there are two sites with the same y -coordinate. It is not difficult to see that these events can be handled in any order when their x -coordinates are distinct. So we can break ties between events with the same y -coordinate but with different x -coordinates arbitrarily. Now suppose there are event points that coincide. For instance, there will be several coincident circle events when there are four or more co-circular sites, such that the interior of the circle through them is empty. The center of this circle is a vertex of the Voronoi diagram. The degree of this vertex is at least four. We could write special code to handle such degenerate cases, but there is no need to do so. What will happen if we let the algorithm handle these events in arbitrary order? Instead of producing a vertex with degree four, it will just produce two vertices with degree three at the same location, with a zero length edge between them. These degenerate edges can be removed in a post-processing step, if required.

Besides these degeneracies in choosing the order of the events we may also encounter degeneracies while handling an event. This occurs when a site p_i that we process happens to be located exactly below the breakpoint between two arcs on the beach line. In this case the algorithm splits either of these two arcs and inserts the arc for p_i in between the two pieces, one of which has zero length. This piece of zero length now is the middle arc of a triple that defines a circle event. The lowest point of this circle coincides with p_i . The algorithm inserts this circle event into the event queue Q , because there are three consecutive arcs on the beach line that define it. When this circle event is handled, a vertex of the Voronoi diagram is correctly created and the zero length arc can be deleted later.

We conclude that the above algorithm handles degenerate cases correctly.

Theorem 7.10 *The Voronoi diagram of a set of n point sites in the plane can be computed with a sweep line algorithm in $O(n \log n)$ time using $O(n)$ storage.*

7.3 Notes and Comments

Although it is beyond the scope of this book to give an extensive survey of the history of Voronoi diagrams it is appropriate to make a few historical remarks. Voronoi diagrams are often attributed to Dirichlet [122]—hence the name *Dirichlet tessellations* that is sometimes used—and Voronoi [328, 329]. They can already be found in Descartes's treatment of cosmic fragmentation in Part III of his *Principia Philosophiae*, published in 1644. Also in this century the Voronoi diagram has been re-discovered several times. In biology this even happened twice in a very short period. In 1965 Brown [54] studied the intensity of trees in a forest. He defined the *area potentially available* to a tree, which was in fact the Voronoi cell of that tree. One year later Mead [238] used the same concept for plants, calling the Voronoi cells *plant polygons*. By now there is an impressive amount of literature concerning Voronoi diagrams and their applications in all kinds of research areas. The book by Okabe et

al. [261] contains an ample treatment of Voronoi diagrams and their applications. We confine ourselves in this section to a discussion of the various aspects of Voronoi diagrams encountered in the computational geometry literature.

In this chapter we have proved some properties of the Voronoi diagram, but it has many more. For example, if one connects all the pairs of sites whose Voronoi cells are adjacent then the resulting set of segments forms a triangulation of the point set, called the Delaunay triangulation. This triangulation, which has some very nice properties, is the topic of Chapter 9.

There is a beautiful connection between Voronoi diagrams and convex polyhedra. Consider the transformation that maps a point $p = (p_x, p_y)$ in \mathbb{E}^2 to the non-vertical plane $h(p) : z = 2p_x x + 2p_y y - (p_x^2 + p_y^2)$ in \mathbb{E}^3 . Geometrically, $h(p)$ is the plane that is tangent to the unit paraboloid $U : z = x^2 + y^2$ at the point vertically above $(p_x, p_y, 0)$. For a set P of point sites in the plane, let $H(P)$ be the set of planes that are the images of the sites in P . Now consider the convex polyhedron P that is the intersection of all positive half-spaces defined by the planes in $H(P)$, that is, $P := \bigcap_{h \in H(P)} h^+$, where h^+ denotes the half-space above h . Surprisingly, if we project the edges and vertices of the polyhedron vertically downwards onto the xy -plane, we get the Voronoi diagram of P [138]. See Chapter 11 for a more extensive description of this transformation.

We have studied Voronoi diagrams in their most basic setting, namely for a set of point sites in the Euclidean plane. The first optimal $O(n \log n)$ time algorithm for this case was a divide-and-conquer algorithm presented by Shamos and Hoey [311]; since then many other optimal algorithms have been developed. The plane sweep algorithm that we described is due to Fortune [152]. Fortune's original description of the algorithm is a little different from ours, which follows the interpretation of the algorithm given by Guibas and Stolfi [172].

Voronoi diagrams can be generalized in many ways [16, 261]. One generalization is to point sets in higher-dimensional spaces. In \mathbb{E}^d the maximum combinatorial complexity of the Voronoi diagram of a set of n point sites (the maximum number of vertices, edges, and so on, of the diagram) is $\Theta(n^{\lfloor d/2 \rfloor})$ [203] and it can be computed in $O(n \log n + n^{\lfloor d/2 \rfloor})$ optimal time [72, 111, 309]. The fact that the dual of the Voronoi diagram is a triangulation of the set of sites, and the connection between Voronoi diagrams and convex polyhedra as discussed above, still hold in higher dimensions.

Another generalization concerns the metric that is used. In the L_1 -metric or Manhattan metric, the distance between two points p and q is defined as

$$\text{dist}_1(p, q) := |p_x - q_x| + |p_y - q_y|;$$

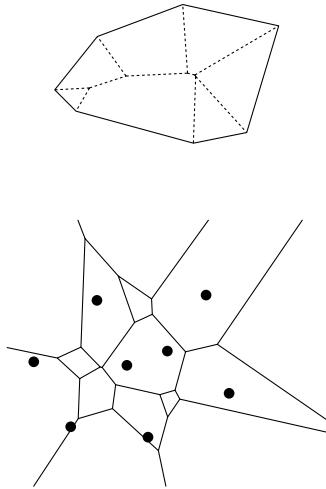

the sum of the absolute differences in the x - and y -coordinates. In a Voronoi diagram in the L_1 -metric, all edges are horizontal, vertical, or diagonal (an angle of 45° with the coordinate axes). In the more general L_p -metric, the distance between two points p and q is defined as

$$\text{dist}_p(p, q) := \sqrt[p]{|p_x - q_x|^p + |p_y - q_y|^p}.$$

Note that the L_2 -metric is simply the Euclidean metric. There are several papers dealing with Voronoi diagrams in these metrics [96, 213, 217]. One can also define a distance function by assigning weights to the sites: a multiplicative weight and an additive weight. Now the distance of a site to a point is its multiplicative weight times the Euclidean distance to the point, plus its additive weight. The resulting diagrams are called weighted Voronoi diagrams [17]. Power diagrams [13, 14, 15, 18] are another generalization of Voronoi diagrams where a different distance function is used. It is even possible to drop the distance function altogether and define the Voronoi diagram in terms of bisectors between any two sites only. Such diagrams are called abstract Voronoi diagrams [204, 205, 206, 240].

Other generalizations concern the shape of the sites. Such generalizations occur when the Voronoi diagram is used for motion planning purposes. An important special case is the Voronoi diagram of the edges of a simple polygon, interior to the polygon itself. This Voronoi diagram is also known as the medial axis or skeleton, and it has applications in shape analysis. The medial axis can be computed in time linear in the number of edges of the polygon [101].

Instead of partitioning the space into regions according to the closest sites, one can also partition it according to the k closest sites, for some $1 \leq k \leq n - 1$. The diagrams obtained in this way are called higher-order Voronoi diagrams, and for given k the diagram is called the order- k Voronoi diagram [1, 19, 50, 77]. Note that the order-1 Voronoi diagram is nothing more than the standard Voronoi diagram. The order- $(n - 1)$ Voronoi diagram is also called the farthest-point Voronoi diagram, because the Voronoi cell of a point p_i now is the region of points for which p_i is the farthest site. The maximum complexity of the order- k Voronoi diagram of a set of n point sites in the plane is $\Theta(k(n - k))$ [214]. Currently the best known algorithm for computing the order- k Voronoi diagram runs in $O(n \log^3 n + k(n - k))$ time [1].

7.4 Exercises

- 7.1 Prove that for any $n > 3$ there is a set of n point sites in the plane such that one of the cells of $\text{Vor}(P)$ has $n - 1$ vertices.
- 7.2 Show that Theorem 7.3 implies that the average number of vertices of a Voronoi cell is less than six.
- 7.3 Show that $\Omega(n \log n)$ is a lower bound for computing Voronoi diagrams by reducing the sorting problem to the problem of computing Voronoi diagrams. You can assume that the Voronoi diagram algorithm should be able to compute for every vertex of the Voronoi diagram its incident edges in cyclic order around the vertex.
- 7.4 Prove that the breakpoints of the beach line, as defined in Section 7.2, trace out the Voronoi diagram while the sweep line moves from top to bottom.

- 7.5 Give an example where the parabola defined by some site p_i contributes more than one arc to the beach line. Can you give an example where it contributes a linear number of arcs?
- 7.6 Give an example of six sites such that the plane sweep algorithm encounters the six site events before any of the circle events.
- 7.7 Do the breakpoints of the beach line always move downwards? Prove this or give a counterexample.
- 7.8 Write a procedure to compute a big enough bounding box from the incomplete doubly-connected edge list and the tree T after the sweep is completed. The box should contain all sites and all Voronoi vertices.
- 7.9 Write a procedure to add all cell records and the corresponding pointers to the incomplete doubly-connected edge list after the bounding box has been added.
- 7.10 Let P be a set of n points in the plane. Give an $O(n \log n)$ time algorithm to find two points in P that are closest together. Show that your algorithm is correct.
- 7.11 Let P be a set of n points in the plane. Give an $O(n \log n)$ time algorithm to find for each point p in P another point in P that is closest to it.
- 7.12 Let the Voronoi diagram of a point set P be stored in a doubly-connected edge list as it is computed in this chapter, inside a bounding box. Give an algorithm to compute the convex hull of P in time linear in the output size.
- 7.13* In the Voronoi assignment model the goods or services that the consumers want to acquire have the same market price at every site. Suppose this is not the case, and that the price of the good at site p_i is w_i . The trading areas of the sites now correspond to the cells in the weighted Voronoi diagram of the sites (see Section 7.3), where site p_i has an additive weight w_i . Generalize the sweep line algorithm of Section 7.2 to this case.
- 7.14* Suppose that we are given a subdivision of the plane into n convex regions. We suspect that this subdivision is a Voronoi diagram, but we do not know the sites. Develop an algorithm that finds a set of n point sites whose Voronoi diagram is exactly the given subdivision, if such a set exists.
